

Intelligent Reflecting Surface-Aided SWIPT: Joint Waveform, Active and Passive Beamforming Design

Yang Zhao, *Member, IEEE*, Bruno Clerckx, *Senior Member, IEEE* and Zhenyuan Feng, *Member, IEEE*

Abstract—The performance of Simultaneous Wireless Information and Power Transfer (SWIPT) is mainly restricted by the strength of the received Radio-Frequency (RF) signal. To tackle this problem, we introduce a low-power Intelligent Reflecting Surface (IRS) that compensates the propagation loss and boosts the energy efficiency by provide a passive beamforming gain. This paper investigates an IRS-aided SWIPT system where a multi-carrier multi-antenna Access Point (AP) transmits information and power simultaneously to a single-antenna user under the assist of an IRS. Considering the rectifier nonlinearity, we aim to maximize the Rate-Energy (R-E) region through a joint optimization of the transmit waveform and active beamforming at the AP, the reflection coefficients at the IRS, and the power splitting ratio at the user. Stationary solutions are achieved based on Alternating Optimization (AO) technique, where the optimal active beamforming is obtained in closed form, the passive beamforming is optimized by Successive Convex Approximation (SCA) technique, and the waveform and splitting ratio are optimized by Geometric Programming (GP) technique. It is confirmed that due to rectifier nonlinearity, a dedicated power signal can be beneficial to energy harvesting (EH), such that the Time-Switching (TS) receiver is preferred over Power-Splitting (PS) receiver for multi-carrier transmission at a low Signal-to-Noise Ratio (SNR). Simulation results also show that the introduction of IRS significantly enlarges the R-E region while preserving the waveform preference and transceiving strategy. Although the AP-IRS-user extra link is relatively weak, we found that the information and power benefits of passive beamforming scale much faster than those of active beamforming. It suggests using more active antennas for small-scale SWIPT and more passive elements for large-scale SWIPT.

Index Terms—Wireless information and power transfer, intelligent reflecting surface, waveform design, active and passive beamforming.

I. INTRODUCTION

A. Simultaneous Wireless Information and Power Transfer

WITH the great advance in communication performance, a bottleneck of wireless networks has come to energy supply. Most existing mobile devices are powered by batteries that require frequent charging or replacement, which causes high maintenance cost and restricts the scale of networks. Although solar energy and inductive coupling have become popular alternatives, the former depends on the environment while the latter has a very short operation range. Simultaneous Wireless Information and Power Transfer (SWIPT) is a promising solution to connect and power mobile devices via electromagnetic (EM) waves in the Radio-Frequency (RF) band. It provides low power at μW level but broad coverage up to

hundreds of meters in a sustainable and controllable manner, bringing more opportunities to the Internet of Things (IoT) and Machine to Machine (M2M) networks. The upsurge in the number of connected devices, together with the decreasing trend in the power consumption of electronics, call for a re-thinking of future wireless networks based on Wireless Power Transfer (WPT) and SWIPT [1].

The concept of SWIPT was first cast in [2], where the authors investigated the Rate-Energy (R-E) tradeoff for a flat Gaussian channel and typical discrete channels. Two co-localized information and power receivers were then proposed in [3], namely Time Switching (TS) that switches between Energy Harvesting (EH) and Information Decoding (ID) modes, and Power Splitting (PS) that splits the received signal into individual components. Dedicated information and energy beamforming were then investigated in [4], [5] to characterize the R-E region for multi-antenna broadcast and interference channels. On the other hand, [6] pointed out that the RF-to-Direct Current (DC) conversion efficiency depends on the rectifier input power level and input waveform shape. It implies that the modeling of the energy harvester, in particular its nonlinearity, has a crucial and significant impact on the waveform preference, resource allocation and system design of any wireless-powered systems [1], [6], [7]. Motivated by this, [8] derived a tractable nonlinear harvester model based on the Taylor expansion of diode I-V characteristics, then designed joint waveform and beamforming design for WPT. Simulation and experiments demonstrated that ignoring the energy harvester nonlinearity is inaccurate and emphasized the benefit of modeling such nonlinearity in real system design [9], [10]. Importantly, the joint waveform and beamforming strategy for WPT was also shown experimentally in [11] to be a key technique to expand the operation range. Beyond WPT, the work in [8] was extended to SWIPT in [12]. Uniquely, it showed that the rectifier nonlinearity leads to radical changes to SWIPT design, namely 1) modulated and unmodulated waveforms are not equally suitable for wireless power delivery, 2) a multi-carrier unmodulated waveform superposed to a multi-carrier modulated waveform is useful to enlarge the R-E region of SWIPT, 3) a combination of PS and TS is in general the best strategy, 4) the optimal input distribution is not the conventional Circularly Symmetric Complex Gaussian (CSCG), 5) the rectifier nonlinearity is beneficial to system performance and is essential to efficient SWIPT design. Those observations, validated experimentally in [9], led to the question "what is the optimal input distribution for SWIPT under nonlinearity?". This question was answered in [13] for single-carrier SWIPT, and some attempts were further made in [14] for multi-carrier

The authors are with the Department of Electrical and Electronic Engineering, Imperial College London, London SW7 2AZ, U.K. (e-mail: {yang.zhao18, b.clerckx, zhenyuan.feng19}@imperial.ac.uk).

SWIPT. The answer sheds new light to fundamental limits of SWIPT and practical signaling (e.g. modulation and waveform) strategies. It is now well understood from [12]–[14] that, due to the nonlinearity, a combination of CSCG and On-Off Keying in single-carrier setting and non-zero mean and asymmetric inputs in multi-carrier setting lead to significantly larger R-E region compared to conventional CSCG. Recently, [15] used machine learning techniques to design SWIPT signaling under nonlinearity to complement the information theoretic results of [13] and new modulation schemes were subsequently designed.

B. Intelligent Reflecting Surface

Intelligent Reflecting Surface (IRS) has recently emerged as a promising technique that adapts the wireless channel to increase spectrum and energy efficiency. In practice, an IRS consists of multiple individual reflecting elements that adjust the amplitude and phase of the incident signal through passive beamforming. Different from relay and backscatter, IRS assists the primary transmission using fully passive components, thus consumes less power with no additional thermal noise but is limited to Frequency-Flat (FF) reflection. Although Frequency-Selective Surface (FSS) has received much attention for wideband communications, it is different from IRS as active FSS requires RF-chains [16] while passive FSS has fixed physical characteristics and is non-adaptive [17].

Inspired by the development of real-time reconfigurable metamaterials [18], the authors of [19] introduced a programmable metasurface that steers or polarizes the EM wave at specific frequency to mitigate signal attenuation. Motivated by this, [20] proposed an IRS-assisted Multiple-Input Single-Output (MISO) system and jointly optimized the precoder at the Access Point (AP) and the phase shifts at the IRS to minimize the transmit power. The active and passive beamforming problem was extended to the discrete phase shift case [21] and the multiuser case [22]. Starting from the impedance equation, [23] investigated the influence of phase shift on the reflection amplitude and proposed a parametric IRS model via curve fitting. In [24], channel estimation for Time-Division Duplex (TDD) systems was carried through a two-stage Minimum Mean Squared Error (MMSE)-based protocol that sequentially estimates the cascaded channel of each reflector with the others switched off. To reduce estimation overhead and design complexity, [25] exploited the spatial correlation and proposed a group-based IRS model where adjacent elements share a common reflection coefficient. Recent research also explored the possibility of integrating IRS into Orthogonal Frequency-Division Multiplexing (OFDM) systems. For example, [26] further enhances time diversity by dynamic passive beamforming that varies IRS over consequent time slots, to enable flexible resource allocation over time-frequency Resource Blocks (RBs). In [27], a prototype IRS with 256 2-bit elements based on Positive Intrinsic-Negative (PIN) diodes was developed to support real-time high-definition video transmission at GHz and mmWave frequency.

C. IRS-Aided SWIPT

The effective channel enhancement and low power consumption of IRS are expected to bring more opportunities to SWIPT.

It was argued in [28] that dedicated energy beam is power-inefficient and may cause interference, thus not required to maximize the Weighted Sum-Power (WSP) for a multiuser IRS-assisted SWIPT system. On the other hand, [29] suggested that if the interference can be cancelled, multiple energy beams are generally required for the max-min harvested power problem. [30] proposed a novel penalty-based algorithm, whose inner layer employs Block Coordinate Descent (BCD) method to update transmit precoders and IRS phase shifts while the outer layer updates the penalty coefficients. It demonstrated that Line-of-Sight (LoS) links can boost the harvested power because the rank-deficient channels are highly correlated. In such cases, a single energy stream is enough for all energy receivers. However, to the best of the authors' knowledge, all existing IRS-assisted SWIPT papers focus on single-carrier transmission and on an inaccurate and oversimplified linear energy harvester model.

In this paper, we marry the benefits of joint multi-carrier waveform and active beamforming optimization for SWIPT (accounting for nonlinearity) with the passive beamforming capability of IRS. The contribution of the paper are listed as follows.

First, we introduce a novel IRS-aided SWIPT architecture based on a joint waveform, active and passive beamforming design. This architecture can be seen to IRS-aided SWIPT what [12] is to SWIPT. Specifically, we consider a multi-carrier IRS-aided downlink MISO SWIPT system where the IRS assists the information and energy transmission of a single user. A multi-carrier unmodulated power waveform (deterministic multisine) is superposed to a multi-carrier modulated information waveform to boost the energy transfer efficiency. The power and information waveforms and active beamforming at the transmitter, the phase shifts at the IRS, and the splitting ratio at the receiver are jointly optimized to maximize the R-E tradeoff while accounting for the rectenna nonlinearity. This is the first paper to propose such a joint waveform, active and passive beamforming architecture for IRS-aided SWIPT. Note that existing IRS-aided SWIPT papers [28]–[31] focus on single-carrier transmissions and ignore the rectenna nonlinearity (and therefore assume the oversimplified and inaccurate linear model), which prevents from exploiting the waveform gain in SWIPT system design. On the contrary, this paper focus on multi-carrier IRS-SWIPT and investigates the fundamental impact of harvester nonlinearity on joint waveform, active and passive beamforming design.

Second, we formulate an optimization for this joint waveform, active and passive beamforming design so as to characterize the R-E region achieved by the proposed architecture. The R-E region characterization problem is transformed into multiple energy maximization problems subject to rate constraints. Each achievable R-E pair is obtained through an Alternating Optimization (AO) algorithm that iteratively updates 1) phase shift at the IRS, 2) waveform and active beamforming at the transmitter and power splitting ratio at the receiver, until convergence. On top of the SWIPT optimization based on Geometric Programming (GP) [12], our IRS-aided SWIPT optimization employs an low-complexity passive beamforming algorithm based on Successive Convex Approximation (SCA)

and Semidefinite Relaxation (SDR), which solves the highly non-convex problem in an efficient and reliable manner. Though no rigorous mathematical proof exists for the convergence of the relaxed IRS phase shift problem, numerical results demonstrated SDR is tight and the proposed algorithm can always find a stationary point for all tested channel realizations under different configurations.

Third, we conduct numerical evaluations that demonstrate the benefit of the proposed architecture. It is confirmed that the observations for SWIPT carries on to IRS-aided SWIPT. For example, dedicated power waveform can boost the energy transmission efficiency for multi-carrier transmission, while TS and PS are preferred at low and high SNR, respectively. Results also confirmed that the IRS bring a significant channel amplification and R-E enhancement with no impact on the waveform preference and transceiving strategy. Different from the active amplify-and-forward relay with optimal location around the midpoint [32], the passive IRS should be placed next to either the transmitter or the receiver, due to the product-distance path loss model. It implies that that equipping the AP with an IRS can effectively extend the operation range of SWIPT systems. For active beamforming, increasing the number of transmit antennas brings a linear growth in SNR and a quadratic boost in harvested DC power. For passive beamforming, increasing the number of reflect elements provides a quadratic growth in SNR and a quartic boost in harvested DC power. Moreover, the adaptive IRS design outperforms the non-adaptive (rate/energy-optimized) ones for broadband transmission, while the performance of all three strategies coincides with the ideal Frequency-Selective (FS) IRS for narrowband transmission.

Organization: The rest of this paper is organized as follows. Section II introduces the signal, channel, receiver and R-E tradeoff models of the IRS-aided SWIPT system. Section III tackles the waveform, active and passive beamforming optimization. Section IV presents simulation results to evaluate the proposed design. Section V concludes the paper.

Notations: Scalars are denoted by italic letters, vectors are denoted by bold lower-case letters, and matrices are denoted by bold upper-case letters. j refers to the imaginary unit. $\mathbb{C}^{x \times y}$ denotes the subspace spanned by complex $x \times y$ matrices. $\Re\{\cdot\}$ and $\Im\{\cdot\}$ stand for the real and imaginary part of a complex number or variable, respectively. $(\cdot)^*$, $(\cdot)^T$ and $(\cdot)^H$ represent the conjugate, transpose, and conjugate transpose operators, respectively. $\mathcal{A}\{\cdot\}$ extracts the DC component of a signal, and $\mathcal{E}_X\{\cdot\}$ takes the expectation over the distribution of the random variable X (X may be omitted for simplicity). For a scalar x , $|x|$ denotes its absolute value. For a vector \mathbf{x} , $\|\mathbf{x}\|$ refers to its Euclidean norm, $\arg(\mathbf{x})$ refers to its argument vector, and $\text{diag}(\mathbf{x})$ refers to a square diagonal matrix with the elements of \mathbf{x} on the main diagonal. For a general matrix \mathbf{M} , $\text{rank}(\mathbf{M})$ denotes its rank. For a square matrix \mathbf{S} , $\text{Tr}(\mathbf{S})$ denotes its trace, and $\mathbf{S} \succeq 0$ means that \mathbf{S} is positive semi-definite. The distribution of a CSCG random vector with mean vector $\mathbf{0}$ and covariance matrix Σ is denoted by $\mathcal{CN}(\mathbf{0}, \Sigma)$, and \sim stands for "distributed as". We also denote $(\cdot)^*$ and $(\cdot)^{(i)}$ as stationary solution and solution at iteration i , respectively.

Fig. 1. An IRS-aided OFDM SWIPT system.

II. SYSTEM MODEL

As shown in Fig. 1, we consider an IRS-aided SWIPT system where a M -antenna AP delivers information and power simultaneously, through a L -reflector IRS, to a single-antenna user over N orthogonal evenly-spaced subbands with center frequency f_n ($n = 1, \dots, N$). Perfect Channel State Information (CSI) at the transmitter, IRS and receiver with negligible training overhead are assumed to explore the upper bound of the proposed design. A quasi-static block fading channel model is considered for all links, and we focus on one particular block where the channels are approximately unchanged. Two practical co-located receiver architectures are compared in terms of R-E region. Specifically, TS divides each time slot into orthogonal data and energy slots and performs a time sharing between WPT and Wireless Information Transfer (WIT). In comparison, PS splits the received signal into individual ID and EH streams such that the splitting ratio ρ is coupled with waveform and beamforming design. Perfect synchronization is assumed among the three parties in both scenarios, and signals reflected by IRS for two and more times are omitted. We also assume the noise power is too small to be harvested.

A. Transmit Signal

Denote $\tilde{x}_{I,n}(t)$ as the information symbol transmitted over subband n satisfying $\tilde{x}_{I,n} \sim \mathcal{CN}(0, 1)$. The superposed transmit signal on antenna m ($m = 1, \dots, M$) at time t is

$$x_m(t) = \Re \left\{ \sum_{n=1}^N (w_{I,n,m} \tilde{x}_{I,n}(t) + w_{P,n,m}) e^{j2\pi f_n t} \right\} \quad (1)$$

where $w_{I/P,n,m}$ denotes the weight of the information and power signal transmitted by antenna m at subband n .

Stacking up the entries on all antennas, we define $\mathbf{w}_{I/P,n} = [w_{I/P,n,1}, \dots, w_{I/P,n,M}]^T \in \mathbb{C}^{M \times 1}$ and $\mathbf{x}(t) = \mathbf{x}_I(t) + \mathbf{x}_P(t)$, where

$$\mathbf{x}_I(t) = \Re \left\{ \sum_{n=1}^N \mathbf{w}_{I,n} \tilde{x}_{I,n}(t) e^{j2\pi f_n t} \right\}, \quad (2)$$

$$\mathbf{x}_P(t) = \Re \left\{ \sum_{n=1}^N \mathbf{w}_{P,n} e^{j2\pi f_n t} \right\}. \quad (3)$$

B. Composite Channel

At subband n , denote the AP-user direct channel as $\mathbf{h}_{D,n}^H \in \mathbb{C}^{1 \times M}$, AP-IRS incident channel as $\mathbf{H}_{I,n} \in \mathbb{C}^{L \times M}$, and IRS-user reflective channel as $\mathbf{h}_{R,n}^H \in \mathbb{C}^{1 \times L}$. At the IRS, element l ($l = 1, \dots, L$) redistributes the incoming signal by adjusting the reflection coefficient $\phi_l = \alpha_l e^{j\theta_l}$ with reflection amplitude $\alpha_l \in [0, 1]$ and phase shift $\theta_l \in [0, 2\pi)$ ¹. Define the IRS matrix as $\mathbf{\Theta} = \text{diag}(\phi_1, \dots, \phi_L) \in \mathbb{C}^{L \times L}$ that collects the reflection coefficients onto its main diagonal entries. The extra link introduced by IRS can be modeled as a concatenation of the AP-IRS incident channel, IRS reflection matrix, and IRS-user reflective channel. On top of this, the total composite channel is obtained by superposing the IRS-aided extra channel to the AP-user direct channel as

$$\mathbf{h}_n^H = \mathbf{h}_{D,n}^H + \mathbf{h}_{R,n}^H \mathbf{\Theta} \mathbf{H}_{I,n} = \mathbf{h}_{D,n}^H + \phi^H \mathbf{V}_n \quad (4)$$

where $\phi = [\phi_1, \dots, \phi_L]^H \in \mathbb{C}^{L \times 1}$ and $\mathbf{V}_n = \text{diag}(\mathbf{h}_{R,n}^H) \mathbf{H}_{I,n} \in \mathbb{C}^{L \times M}$. Note the conjugate transpose in the notation of ϕ makes its entries the complex conjugate of the diagonal entries of $\mathbf{\Theta}$.

Remark 1. The IRS reflection coefficients are constant across the frequency, i.e. the IRS is frequency-flat where independent phase shift control over subbands are prohibited due to hardware constraints.

C. Receive Signal

At the single-antenna receiver, the total received signal $y(t) = y_I(t) + y_P(t)$ captures the contribution from information and power components over N subbands, where

$$y_I(t) = \Re \left\{ \sum_{n=1}^N \mathbf{h}_n^H \mathbf{w}_{I,n} \tilde{x}_{I,n}(t) e^{j2\pi f_n t} \right\}, \quad (5)$$

$$y_P(t) = \Re \left\{ \sum_{n=1}^N \mathbf{h}_n^H \mathbf{w}_{P,n} e^{j2\pi f_n t} \right\}. \quad (6)$$

D. Information Decoder

A major benefit of the superposed waveform is that the multisine power waveform creates no interference to the information waveform. Therefore, the achievable rate writes as

$$R(\phi, \mathbf{w}_I, \rho) = \sum_{n=1}^N \log_2 \left(1 + \frac{(1-\rho) |\mathbf{h}_n^H \mathbf{w}_{I,n}|^2}{\sigma_n^2} \right) \quad (7)$$

where ρ is the power splitting ratio for the energy harvester, σ_n^2 is the variance of the total noise (at RF-band and during RF-to-baseband conversion) on tone n . Rate (7) is achievable with either waveform cancellation or translated demodulation [12].

E. Energy Harvester

In this section, we briefly revisit a tractable nonlinear rectenna model that relates the harvester output DC current

¹To investigate the performance upper bound of IRS, we suppose the reflection coefficient is maximized $\alpha_l = 1, \forall l$ while the phase shift is a continuous variable over $[0, 2\pi)$.

Fig. 2. Rectenna circuits.

to the received waveform [8], [12]. Fig. 2a illustrates the equivalent circuit of a lossless antenna, where the incoming signal creates an voltage source $v_s(t)$ and the antenna has an impedance R_{ant} . Let R_{in} be the total input impedance of the rectifier and matching network, and we assume the voltage across matching network is negligible. When perfectly matched ($R_{\text{in}} = R_{\text{ant}}$), the rectifier input voltage is $v_{\text{in}}(t) = y(t) \sqrt{\rho R_{\text{ant}}}$.

Rectifiers consist of nonlinear components as diode and capacitor to produce DC output and store energy [33]. Consider a simplified rectifier model in Fig. 2b where a single series diode is followed by a low-pass filter with a parallel load. Denote i_s as the reverse bias saturation current, n' as the diode ideality factor, v_t as the thermal voltage, $v_d(t) = v_{\text{in}}(t) - v_{\text{out}}(t)$ as the voltage across the diode where $v_{\text{out}}(t)$ is the output voltage across the load. A Taylor expansion of the diode characteristic equation $i_d(t) = i_s(e^{v_d(t)/n'v_t} - 1)$ around a quiescent operating point a writes as $i_d(t) = \sum_{i=0}^{\infty} k'_i (v_d(t) - a)^i$, where $k'_0 = i_s(e^{a/n'v_t} - 1)$ and $k'_i = i_s e^{a/n'v_t} / i! (n'v_t)^i$ for $i = 1, \dots, \infty$. Note that this small-signal expansion model is only valid for the non-linear operation region, and the I-V relationship would be linear if the diode behavior is dominated by the load [8]. Also, an ideal low-pass filter with steady-state response can provide a constant v_{out} that depends on the peak of $v_{\text{in}}(t)$ [34]. Therefore, a proper choice of the operating voltage drop is $a = \mathcal{E}\{v_d(t)\} = -v_{\text{out}}$ such that

$$i_d(t) = \sum_{i=0}^{\infty} k'_i \rho^{i/2} R_{\text{ant}}^{i/2} y(t)^i. \quad (8)$$

By discarding the non-DC components, taking expectation over symbol distribution, and truncating (8) to the n_0 -th order, we approximate the average output DC current for a given channel as

$$i_{\text{out}}(t) = \mathcal{A}\{i_d(t)\} \approx \sum_{i=0}^{n_0} k'_i \rho^{i/2} R_{\text{ant}}^{i/2} \mathcal{E}\{\mathcal{A}\{y(t)^i\}\}. \quad (9)$$

With the assumption of evenly-spaced frequencies, it holds that $\mathcal{A}\{y(t)^i\} = 0$ for odd i thus the related terms have no contribution to DC output. However, k'_i is still a function of i_{out} , and [8] proved that maximizing a truncated i_{out} is equivalent to maximizing a monotonic function

$$z(\phi, \mathbf{w}_I, \mathbf{w}_P, \rho) = \sum_{i \text{ even}, i \geq 2}^{n_0} k_i \rho^{i/2} R_{\text{ant}}^{i/2} \mathcal{E}\{\mathcal{A}\{y(t)^i\}\} \quad (10)$$

where $k_i = i_s / i! (n'v_t)^i$. It can be observed that the traditional linear harvester model, where the output DC power equals the sum of the power harvested on each frequency, is a special case of (10) with $n_0 = 2$. However, due to the coupling among different frequencies, some high-order AC

Fig. 3. $\mathbf{W}_{I/P}$ consists of $N \times N$ blocks of size $M \times M$. $\mathbf{W}_{I/P,k}$ keeps the k -th block diagonal of $\mathbf{W}_{I/P}$ and nulls all remaining blocks. Solid, dashed and dotted blocks correspond to $k > 0$, $k = 0$ and $k < 0$, respectively. For $\mathbf{w}_{I/P,n_1} \mathbf{w}_{I/P,n_2}^H$, the k -th block diagonal satisfies $k = n_2 - n_1$.

components compensate each other and further contribute to the output DC power. In other words, even-order terms with $i \geq 4$ account for the nonlinear behavior of the diode. For simplicity, we let $\beta_2 = k_2 R_{\text{ant}}$, $\beta_4 = k_4 R_{\text{ant}}^2$ and choose $n_0 = 4$ to investigate fundamental rectifier nonlinearity so that z further reduces to (11). Note that $\mathcal{E}\{|\tilde{x}_{I,n}|^2\} = 1$ but $\mathcal{E}\{|\tilde{x}_{I,n}|^4\} = 2$, which can be interpreted as a modulation gain on the nonlinear terms of the output DC current. Inspired by [35], we stack up channel and waveform vectors over all subbands as $\mathbf{h} = [\mathbf{h}_1^T, \dots, \mathbf{h}_N^T]^T \in \mathbb{C}^{MN \times 1}$ and $\mathbf{w}_{I/P} = [\mathbf{w}_{I/P,1}^T, \dots, \mathbf{w}_{I/P,N}^T]^T \in \mathbb{C}^{MN \times 1}$. On top of this, let $\mathbf{W}_{I/P} = \mathbf{w}_{I/P} \mathbf{w}_{I/P}^H \in \mathbb{C}^{MN \times MN}$. As illustrated by Fig. 3, $\mathbf{W}_{I/P}$ can be divided into $N \times N$ blocks of size $M \times M$, and we let $\mathbf{W}_{I/P,k}$ keep its k -th ($k = -N + 1, \dots, N - 1$) block diagonal and set all other blocks to $\mathbf{0}^{M \times M}$. Hence, the components of the output DC current z can be expressed in (12) – (15).

F. Rate-Energy Region

The achievable R-E region is defined as

$$C_{R_{\text{ID}}-I_{\text{EH}}}(P) \triangleq \left\{ (R_{\text{ID}}, I_{\text{EH}}) : R_{\text{ID}} \leq R, I_{\text{EH}} \leq z, \right.$$

$$\left. \frac{1}{2} (\|\mathbf{w}_I\|^2 + \|\mathbf{w}_P\|^2) \leq P \right\} \quad (16)$$

where P is the average transmit power budget and the coefficient $1/2$ converts the peak power of sine waves to the average power.

III. PROBLEM FORMULATION

We characterize the R-E region through a current maximization problem subject to transmit power, IRS magnitude, and rate constraints

$$\max_{\phi, \mathbf{w}_I, \mathbf{w}_P, \rho} z(\phi, \mathbf{w}_I, \mathbf{w}_P, \rho) \quad (17a)$$

$$\text{s.t.} \quad \frac{1}{2} (\|\mathbf{w}_I\|^2 + \|\mathbf{w}_P\|^2) \leq P, \quad (17b)$$

$$R(\phi, \mathbf{w}_I, \rho) \geq \bar{R}, \quad (17c)$$

$$|\phi_l| = 1, \quad l = 1, \dots, L, \quad (17d)$$

$$0 \leq \rho \leq 1. \quad (17e)$$

Problem (17) is intricate as the variables are coupled and the objective function (17a), the rate constraint (17c), and the IRS magnitude constraint (17d) are non-convex. To reduce the design complexity, we propose a suboptimal AO algorithm that iteratively updates the waveform and active beamforming

$$z(\phi, \mathbf{w}_I, \mathbf{w}_P, \rho) = \beta_2 \rho \left(\mathcal{E} \{ \mathcal{A} \{ y_I^2(t) \} \} + \mathcal{A} \{ y_P^2(t) \} \right) + \beta_4 \rho^2 \left(\mathcal{E} \{ \mathcal{A} \{ y_I^4(t) \} \} + \mathcal{A} \{ y_P^4(t) \} + 6 \mathcal{E} \{ \mathcal{A} \{ y_I^2(t) \} \} \mathcal{A} \{ y_P^2(t) \} \right). \quad (11)$$

$$\mathcal{E} \{ \mathcal{A} \{ y_I^2(t) \} \} = \frac{1}{2} \sum_{n=1}^N (\mathbf{h}_n^H \mathbf{w}_{I,n}) (\mathbf{h}_n^H \mathbf{w}_{I,n})^H = \frac{1}{2} \mathbf{h}^H \mathbf{W}_{I,0} \mathbf{h}, \quad (12)$$

$$\mathcal{E} \{ \mathcal{A} \{ y_I^4(t) \} \} = \frac{3}{4} \left(\sum_{n=1}^N (\mathbf{h}_n^H \mathbf{w}_{I,n}) (\mathbf{h}_n^H \mathbf{w}_{I,n})^H \right)^2 = \frac{3}{4} (\mathbf{h}^H \mathbf{W}_{I,0} \mathbf{h})^2, \quad (13)$$

$$\mathcal{A} \{ y_P^2(t) \} = \frac{1}{2} \sum_{n=1}^N (\mathbf{h}_n^H \mathbf{w}_{P,n}) (\mathbf{h}_n^H \mathbf{w}_{P,n})^H = \frac{1}{2} \mathbf{h}^H \mathbf{W}_{P,0} \mathbf{h}, \quad (14)$$

$$\mathcal{A} \{ y_P^4(t) \} = \frac{3}{8} \sum_{\substack{n_1, n_2, n_3, n_4 \\ n_1 + n_2 = n_3 + n_4}} (\mathbf{h}_{n_1}^H \mathbf{w}_{P,n_1}) (\mathbf{h}_{n_2}^H \mathbf{w}_{P,n_2}) (\mathbf{h}_{n_3}^H \mathbf{w}_{P,n_3}) (\mathbf{h}_{n_4}^H \mathbf{w}_{P,n_4})^H = \frac{3}{8} \sum_{k=-N+1}^{N-1} (\mathbf{h}^H \mathbf{W}_{P,k} \mathbf{h}) (\mathbf{h}^H \mathbf{W}_{P,k} \mathbf{h})^H. \quad (15)$$

at the transmitter, the phase shift at the IRS, and the power splitting ratio at the receiver, until convergence.

A. IRS Phase Shift

In this section, the IRS phase shift ϕ is optimized for any given waveform $\mathbf{w}_{I/P}$ and splitting ratio ρ . We observe that

$$\begin{aligned} |\mathbf{h}_n^H \mathbf{w}_{I,n}|^2 &= \mathbf{w}_{I,n}^H \mathbf{h}_n \mathbf{h}_n^H \mathbf{w}_{I,n} \\ &= \mathbf{w}_{I,n}^H (\mathbf{h}_{D,n} + \mathbf{V}_n^H \phi) (\mathbf{h}_{D,n}^H + \phi^H \mathbf{V}_n) \mathbf{w}_{I,n} \\ &= \mathbf{w}_{I,n}^H \mathbf{M}_n^H \Phi \mathbf{M}_n \mathbf{w}_{I,n} \\ &= \text{Tr}(\mathbf{M}_n \mathbf{w}_{I,n} \mathbf{w}_{I,n}^H \mathbf{M}_n^H \Phi) \\ &= \text{Tr}(\mathbf{C}_n \Phi) \end{aligned} \quad (18)$$

where t is an auxiliary variable with unit modulus, $\mathbf{M}_n = [\mathbf{V}_n^H, \mathbf{h}_{D,n}^H]^H \in \mathbb{C}^{(L+1) \times M}$, $\bar{\phi} = [\phi^H, t]^H \in \mathbb{C}^{(L+1) \times 1}$, $\Phi = \bar{\phi} \bar{\phi}^H \in \mathbb{C}^{(L+1) \times (L+1)}$, $\mathbf{C}_n = \mathbf{M}_n \mathbf{w}_{I,n} \mathbf{w}_{I,n}^H \mathbf{M}_n^H \in \mathbb{C}^{(L+1) \times (L+1)}$. On the other hand, we define $t_{I/P,k}$ as

$$\begin{aligned} t_{I/P,k} &= \mathbf{h}^H \mathbf{W}_{I/P,k} \mathbf{h} \\ &= \text{Tr}(\mathbf{h} \mathbf{h}^H \mathbf{W}_{I/P,k}) \\ &= \text{Tr}((\mathbf{h}_D + \mathbf{V}^H \phi) (\mathbf{h}_D^H + \phi^H \mathbf{V}) \mathbf{W}_{I/P,k}) \\ &= \text{Tr}(\mathbf{M}^H \Phi \mathbf{M} \mathbf{W}_{I/P,k}) \\ &= \text{Tr}(\mathbf{M} \mathbf{W}_{I/P,k} \mathbf{M}^H \Phi) \\ &= \text{Tr}(\mathbf{C}_{I/P,k} \Phi) \end{aligned} \quad (19)$$

where $\mathbf{V} = [\mathbf{V}_1, \dots, \mathbf{V}_N] \in \mathbb{C}^{L \times MN}$, $\mathbf{M} = [\mathbf{V}^H, \mathbf{h}_D^H]^H \in \mathbb{C}^{(L+1) \times MN}$, $\mathbf{C}_{I/P,k} = \mathbf{M} \mathbf{W}_{I/P,k} \mathbf{M}^H \in \mathbb{C}^{(L+1) \times (L+1)}$.

Therefore, the rate and objective expressions rewrite as

$$\begin{aligned} R(\Phi) &= \sum_{n=1}^N \log_2 \left(1 + \frac{(1-\rho) \text{Tr}(\mathbf{C}_n \Phi)}{\sigma_n^2} \right), \quad (20) \\ z(\Phi) &= \frac{1}{2} \beta_2 \rho (t_{I,0} + t_{P,0}) \\ &\quad + \frac{3}{8} \beta_4 \rho^2 \left(2t_{I,0}^2 + \sum_{k=-N+1}^{N-1} t_{P,k} t_{P,k}^* \right) \\ &\quad + \frac{3}{2} \beta_4 \rho^2 t_{I,0} t_{P,0}. \end{aligned} \quad (21)$$

To maximize non-concave expression (21), we propose a SCA algorithm that approximate the second-order terms by first-order Taylor expansion [36]. Based on the solution at iteration $i-1$, the approximations at iteration i are

$$(t_{I,0}^{(i)})^2 \geq 2t_{I,0}^{(i)} t_{I,0}^{(i-1)} - (t_{I,0}^{(i-1)})^2, \quad (22)$$

$$t_{P,k}^{(i)} (t_{P,k}^{(i)})^* \geq 2\Re \left\{ t_{P,k}^{(i)} (t_{P,k}^{(i-1)})^* \right\} - t_{P,k}^{(i-1)} (t_{P,k}^{(i-1)})^*, \quad (23)$$

$$\begin{aligned} t_{I,0}^{(i)} t_{P,0}^{(i)} &= \frac{1}{4} (t_{I,0}^{(i)} + t_{P,0}^{(i)})^2 - \frac{1}{4} (t_{I,0}^{(i)} - t_{P,0}^{(i)})^2 \\ &\geq \frac{1}{2} (t_{I,0}^{(i)} + t_{P,0}^{(i)}) (t_{I,0}^{(i-1)} + t_{P,0}^{(i-1)}) \\ &\quad - \frac{1}{4} (t_{I,0}^{(i-1)} + t_{P,0}^{(i-1)})^2 - \frac{1}{4} (t_{I,0}^{(i)} - t_{P,0}^{(i)})^2 \end{aligned} \quad (24)$$

which provide lower bounds to the corresponding terms in (21). Hence, the objection function is approximated by $\tilde{z}(\Phi^{(i)})$ in (25), and problem (17) is transformed to

Algorithm 1 SCA: IRS Phase Shift.

$$\max_{\Phi} \quad \tilde{z}(\Phi) \quad (26a)$$

$$\text{s.t.} \quad R(\Phi) \geq \bar{R}, \quad (26b)$$

$$\Phi_{l,l} = 1, \quad l = 1, \dots, L+1, \quad (26c)$$

$$\Phi \succeq 0, \quad (26d)$$

$$\text{rank}(\Phi) = 1. \quad (26e)$$

Problem (26) is not a standard Semidefinite Programming (SDP). If we relax the rank constraint (26e) to formulate a convex problem, there is no guarantee Φ^* is rank-1, and the optimal rank-1 solution $\bar{\phi}^*$ extracted from Φ^* may not be a stationary point of the original problem (17). In Section IV, we numerically show that Φ^* is rank-1 for all tested channel realizations under different configurations such that the performance loss by SDR is insignificant. A related version of problem (26) can be solved using existing optimization tools such as CVX [37].

When Φ^* is rank-1, the optimal phase shift vector $\bar{\phi}^*$ can be obtained by Eigenvalue Decomposition (EVD). Otherwise, a suboptimal solution can be extracted via Gaussian randomization method [38]. Specifically, we perform EVD $\Phi^* = \mathbf{U} \Sigma \mathbf{U}^H$, generate Q CSCG random vectors $\mathbf{r}_q \sim \mathcal{CN}(\mathbf{0}, \mathbf{I}_{L+1})$, $q = 1, \dots, Q$, construct the corresponding candidates $\bar{\phi}_q = e^{j \arg(\mathbf{U} \Sigma^{1/2} \mathbf{r}_q)}$, and choose the one that maximizes the objective function (26a). Finally, the phase shift is retrieved by $\theta_l^* = \arg(\phi_l^* / \phi_{L+1}^*)$, $l = 1, \dots, L$. The SCA algorithm for passive beamforming optimization is summarized in Algorithm 1.

B. Waveform and Splitting Ratio

Next, we jointly optimize both information and power waveforms $\mathbf{w}_{I/P}$ together with splitting ratio ρ for any given IRS phase shift ϕ . As pointed out in [12], the waveform design in frequency and spatial domain can be decoupled without

performance loss, and the optimal spatial weight is given by Maximum-Ratio Transmission (MRT) beamformer

$$\mathbf{w}_{I/P,n} = s_{I/P,n} \frac{\mathbf{h}_n}{\|\mathbf{h}_n\|}. \quad (27)$$

That is to say, for single-user MISO SWIPT, the optimal active beamformer is MRT and we only need to determine the amplitudes $s_{I/P,n}$ at different tones. Hence, the original waveform optimization with $2MN$ complex variables is converted into a power allocation problem with $2N$ nonnegative real variables. Let $\mathbf{s}_{I/P} = [s_{I/P,1}, \dots, s_{I/P,N}]^T \in \mathbb{C}^{N \times 1}$. At subband n , the effective channel gain is given by $\|\mathbf{h}_n\|$, and the power allocated to the modulated and unmodulated waveform are given by $s_{I,n}^2$ and $s_{P,n}^2$, respectively. With such an active beamformer selection, we have $\mathbf{h}_n^H \mathbf{w}_{I,n} = |\mathbf{h}_n^H \mathbf{w}_{I,n}| = \|\mathbf{h}_n\| s_{I,n}$ such that the rate and objective function further reduces to (28) and (29), respectively.

$$R(\mathbf{s}_I, \rho) = \log_2 \left(\prod_{n=1}^N \left(1 + \frac{(1-\rho)\|\mathbf{h}_n\|^2 s_{I,n}^2}{\sigma_n^2} \right) \right). \quad (28)$$

Therefore, problem (17) is reduced to an amplitude optimization issue

$$\max_{\mathbf{s}_I, \mathbf{s}_P, \rho} z(\mathbf{s}_I, \mathbf{s}_P, \rho) \quad (30a)$$

$$\text{s.t.} \quad \frac{1}{2} (\|\mathbf{s}_I\|^2 + \|\mathbf{s}_P\|^2) \leq P, \quad (30b)$$

$$R(\mathbf{s}_I, \rho) \geq \bar{R}. \quad (30c)$$

Since problem (30) involves the production of nonnegative real variables, we introduce auxiliary variables $t', \bar{\rho}$ and transform it into a reversed GP

$$\min_{\mathbf{s}_I, \mathbf{s}_P, \rho, \bar{\rho}, t'} \frac{1}{t'} \quad (31a)$$

$$\text{s.t.} \quad \frac{1}{2} (\|\mathbf{s}_I\|^2 + \|\mathbf{s}_P\|^2) \leq P, \quad (31b)$$

$$\frac{t'}{z(\mathbf{s}_I, \mathbf{s}_P, \rho)} \leq 1, \quad (31c)$$

$$\frac{2^{\bar{R}}}{\prod_{n=1}^N \left(1 + \bar{\rho} \|\mathbf{h}_n\|^2 s_{I,n}^2 / \sigma_n^2 \right)} \leq 1, \quad (31d)$$

$$\rho + \bar{\rho} \leq 1. \quad (31e)$$

The denominators of (31c), (31d) are posynomials [39] that further decompose as

$$z(\mathbf{s}_I, \mathbf{s}_P, \rho) = \sum_{m_P} g_{m_P}(\mathbf{s}_I, \mathbf{s}_P, \rho), \quad (32)$$

$$1 + \frac{\bar{\rho} \|\mathbf{h}_n\|^2 s_{I,n}^2}{\sigma_n^2} = \sum_{m_{I,n}} g_{m_{I,n}}(s_{I,n}, \bar{\rho}) \quad (33)$$

where $m_P = (2N^3 + 6N^2 + 7N)/3$, $m_{I,n} = 2$ are the number of monomials. Following [40], we upper bound posynomials (32) and (33) by Arithmetic Mean-Geometric Mean (AM-GM) inequality such that problem (31) reduces to

$$\min_{\mathbf{s}_I, \mathbf{s}_P, \rho, \bar{\rho}, t'} \frac{1}{t'} \quad (34a)$$

$$\text{s.t.} \quad \frac{1}{2} (\|\mathbf{s}_I\|^2 + \|\mathbf{s}_P\|^2) \leq P, \quad (34b)$$

$$t' \prod_{m_P} \left(\frac{g_{m_P}(\mathbf{s}_I, \mathbf{s}_P, \rho)}{\gamma_{m_P}} \right)^{-\gamma_{m_P}} \leq 1, \quad (34c)$$

$$2^{\bar{R}} \prod_n \prod_{m_{I,n}} \left(\frac{g_{m_{I,n}}(s_{I,n}, \bar{\rho})}{\gamma_{m_{I,n}}} \right)^{-\gamma_{m_{I,n}}} \leq 1, \quad (34d)$$

$$\rho + \bar{\rho} \leq 1 \quad (34e)$$

where $\gamma_{m_P}, \gamma_{m_{I,n}} \geq 0$, $\sum_{m_P} \gamma_{m_P} = \sum_{m_{I,n}} \gamma_{m_{I,n}} = 1$. The tightness of the AM-GM inequality depends on $\{\gamma_{m_P}, \gamma_{m_{I,n}}\}$

$$\begin{aligned} \tilde{z}(\Phi^{(i)}) &= \frac{1}{2} \beta_2 \rho (t_{I,0}^{(i)} + t_{P,0}^{(i)}) \\ &+ \frac{3}{8} \beta_4 \rho^2 \left(4(t_{I,0}^{(i)})(t_{I,0}^{(i-1)}) - 2(t_{I,0}^{(i-1)})^2 + \sum_{k=-N+1}^{N-1} 2\Re \{ t_{P,k}^{(i)} (t_{P,k}^{(i-1)})^* \} - t_{P,k}^{(i-1)} (t_{P,k}^{(i-1)})^* \right) \\ &+ \frac{3}{2} \beta_4 \rho^2 \left(\frac{1}{2} (t_{I,0}^{(i)} + t_{P,0}^{(i)})(t_{I,0}^{(i-1)} + t_{P,0}^{(i-1)}) - \frac{1}{4} (t_{I,0}^{(i-1)} + t_{P,0}^{(i-1)})^2 - \frac{1}{4} (t_{I,0}^{(i)} - t_{P,0}^{(i)})^2 \right). \end{aligned} \quad (25)$$

$$\begin{aligned} z(\mathbf{s}_I, \mathbf{s}_P, \rho) &= \frac{1}{2} \beta_2 \rho \sum_{n=1}^N \|\mathbf{h}_n\|^2 (s_{I,n}^2 + s_{P,n}^2) \\ &+ \frac{3}{8} \beta_4 \rho^2 \left(2 \sum_{n_1, n_2} \prod_{j=1}^2 \|\mathbf{h}_{n_j}\|^2 s_{I,n_j}^2 + \sum_{\substack{n_1, n_2, n_3, n_4 \\ n_1 + n_2 = n_3 + n_4}} \prod_{j=1}^4 \|\mathbf{h}_{n_j}\| s_{P,n_j} \right) \\ &+ \frac{3}{2} \beta_4 \rho^2 \left(\sum_{n_1, n_2} \|\mathbf{h}_{n_1}\|^2 \|\mathbf{h}_{n_2}\|^2 s_{I,n_1}^2 s_{P,n_2}^2 \right). \end{aligned} \quad (29)$$

Algorithm 2 GP: Waveform, Active Beamforming and Splitting Ratio.

2: initialize  $i \leftarrow 0, \mathbf{s}_{I/P}^{(0)}, \rho^{(0)}$ 
3: repeat
4:    $i \leftarrow i + 1$ 
5:   Update  $\{\gamma_{m_P}^{(i)}, \gamma_{m_{I,n}}^{(i)}\}$  by (35), (36)
6:   Obtain  $\mathbf{s}_{I/P}^{(i)}, \rho^{(i)}$  by solving problem (34)
7:   Compute  $z^{(i)}$  by (29)
8: until  $|z^{(i)} - z^{(i-1)}| \leq \epsilon$ 
9: Set  $\mathbf{s}_{I/P}^* = \mathbf{s}_{I/P}^{(i)}, \rho^* = \rho^{(i)}$ , retrieve  $\mathbf{w}_{I/P}^*$  by (27)
10: output  $\mathbf{w}_{I/P}^*, \rho^*$ 

```

Algorithm 3 AO: Waveform, Active and Passive Beamforming.

```

1: input  $\beta_2, \beta_4, \mathbf{h}_{D,n}, \mathbf{H}_{I,n}, \mathbf{h}_{R,n}, P, \sigma_n, \bar{R}, Q, \epsilon$ 
2: initialize  $i \leftarrow 0, \phi^{(0)}, \mathbf{w}_{I/P}^{(0)}, \rho^{(0)}$ 
3: repeat
4:    $i \leftarrow i + 1$ 
5:   Fix  $\mathbf{w}_{I/P}^{(i-1)}, \rho^{(i-1)}$  and obtain  $\phi^{(i)}$  by Algorithm 1
6:   Fix  $\phi^{(i)}$ , update  $\mathbf{h}_n^{(i)}$  by (4), and obtain  $\mathbf{w}_{I/P}^{(i)}, \rho^{(i)}$  by
     Algorithm 2
7:   Compute  $z^{(i)}$  by (21)
8: until  $|z^{(i)} - z^{(i-1)}| \leq \epsilon$ 
9: output  $\phi^*, \mathbf{w}_{I/P}^*, \rho^*$ 

```

that require successive update. As suggested in [12], a feasible choice at iteration i is

$$\gamma_{m_P}^{(i)} = \frac{g_{m_P}(\mathbf{s}_I^{(i-1)}, \mathbf{s}_P^{(i-1)}, \rho^{(i-1)})}{z(\mathbf{s}_I^{(i-1)}, \mathbf{s}_P^{(i-1)}, \rho^{(i-1)})}, \quad (35)$$

$$\gamma_{m_{I,n}}^{(i)} = \frac{g_{m_{I,n}}(\mathbf{s}_{I,n}^{(i-1)}, \bar{\rho}^{(i-1)})}{1 + \bar{\rho}^{(i-1)} \|\mathbf{h}_n\|^2 (\mathbf{s}_{I,n}^{(i-1)})^2 / \sigma_n^2}. \quad (36)$$

Problem (34) can be solved using existing optimization tools such as CVX [37]. $\mathbf{s}_I, \mathbf{s}_P, \rho$ are updated iteratively until convergence. The GP algorithm of waveform, active beamforming and splitting ratio optimization is summarized in Algorithm 2.

C. Alternating Optimization

For any direct, incident and reflective channels, we iteratively update the passive beamforming by Algorithm 1, and waveform, active beamforming and splitting ratio by Algorithm 2 until convergence. The AO algorithm is summarized in Algorithm 3.

D. Convergence

Proposition 1. *For any feasible initial point, the proposed SCA-based Algorithm 1 can provide a feasible Φ^* that satisfy the KKT conditions, although there is no guarantee Φ^* is rank-1.*

Proof. The objective function (26a) is non-decreasing over iterations because the solution of problem (26) at iteration $i - 1$ is still a feasible point at iteration i . Moreover, the

Fig. 4. System layout in the simulation.

sequence $\{\tilde{z}(\Phi^{(i)})\}_{i=1}^{\infty}$ is bounded above due to the unit-modulus constraint (26c). Thus, Algorithm 1 is guaranteed to converge. To prove $\Phi^{(i)}$ converge to the set of stationary points of IRS subproblem, we notice that the SCA-based Algorithm 1 is indeed an inner approximation algorithm [41], since $\tilde{z}(\Phi) \leq z(\Phi)$, $\partial \tilde{z}(\Phi^{(i)}) / \partial \Phi = \partial z(\Phi^{(i)}) / \partial \Phi$ and the approximation (22) – (24) are asymptotically tight as $i \rightarrow \infty$ [42]. Therefore, Algorithm 1 is guaranteed to provide a feasible Φ^* that satisfy the KKT conditions. \square

Proposition 2. *For any feasible initial point, the GP-based Algorithm 2 is guaranteed to converge to a stationary point of the waveform and splitting ratio subproblem.*

Proof. See [8], [12]. \square

Proposition 3. *Every limit point $(\phi^*, \mathbf{w}_I^*, \mathbf{w}_P^*, \rho^*)$ of the proposed alternating algorithm is a stationary point of the original problem (17).*

Proof. The objective function (17a) is non-decreasing over iterations of Algorithm 3, which is also upper-bounded due to the unit-modulus constraint (17d) and the average transmit power constraint (17b). Thus, Algorithm 3 is guaranteed to converge, namely the sequence $\{\phi^{(i)}, \mathbf{w}_I^{(i)}, \mathbf{w}_P^{(i)}, \rho^{(i)}\}$ generated by optimizing ϕ and $\mathbf{w}_I, \mathbf{w}_P, \rho$ alternatively has limit points. As demonstrated in [43], the solution is a stationary point of problem (17). \square

IV. PERFORMANCE EVALUATIONS

To evaluate the performance of the proposed IRS-aided SWIPT system, we characterize the average R-E regions under typical setups. Consider a large open space WiFi-like environment at a center frequency of 5.18 GHz with reference bandwidth $B = 1$ MHz. As shown in Fig. 4, we assume the IRS moves along a horizontal line parallel to the AP-user path and let d_H, d_V be the horizontal and vertical distances from the AP to the IRS, respectively. We also denote d_D, d_I, d_R as the length of direct, incident, reflective paths such that $d_I = \sqrt{d_H^2 + d_V^2}$, $d_R = \sqrt{(d_D - d_H)^2 + d_V^2}$. Choose as reference $d_D = 15$ m, $d_V = 2$ m and $d_H = 2$ m. The path loss and fading parameters are obtained from IEEE TGN channel model D [44], and reference path loss is set to $L_0 = -35$ dB at $d_0 = 1$ m. We assume all channels are NLoS with taps modelled as i.i.d. CSCG random variables of unit average sum-power to create a normalized multipath response. The reference numbers of transmit antennas, IRS reflectors and subbands are $M = 1, L = 20, N = 16$, respectively. No spatial correlation is considered across transmit antennas and

Fig. 5. Average R-E region versus N for $M = 1$, $L = 20$, $\sigma_n = -40$ dBm, $B = 1$ MHz and $d_H = d_V = 2$ m.

IRS arrays. Rectenna parameters are taken as $k_2 = 0.0034$, $k_4 = 0.3829$, $R_{\text{ant}} = 50 \Omega$. With 0 dBi transmit antenna gain, the average Effective Isotropic Radiated Power (EIRP) is fixed to $P = -36$ dBm while the reference average noise power is $\sigma_n = -40$ dBm at all subbands. We also assume 0 dBi IRS element gain and 2 dBi receive antenna gain. For the algorithm, the tolerance is $\epsilon = 10^{-8}$, the number of candidates in the Gaussian randomization method is $Q = 10^3$, and the R-E region is averaged over 200 channel realizations. In the R-E boundary, the leftmost point corresponds to WPT ($\rho = 1$) where power can be allocated simultaneously to modulated and unmodulated waveform to maximize the average output DC current. On the other hand, the rightmost point corresponds to WIT ($\rho = 0$) where the solution coincides with the Water-Filling (WF) algorithm that allocates all power to modulated waveform only. For a fair comparison, the x -axis of the plots has been normalized to per-subband rate.

We first evaluate the performance of Algorithm 1 under SDR. It is demonstrated that Φ^* is rank-1 for all tested channel realizations with different M , N and L . Therefore, ϕ^* can be directly obtained through EVD and we claim Algorithm 1 converges to stationary points of problem (26) without performance loss.

Fig. 5 illustrates the average R-E region versus the number of subband N . *First*, it is observed that increasing N reduces the per-subband rate but boosts the harvested energy. The reason is that although each subband receives a smaller proportion of the total power, more balanced terms m_P are introduced to further amplify the output DC current, as suggested by the scaling laws in [12]. Sorted waveform amplitudes in Fig. 6 also confirmed that from the perspective of WPT, dedicated multisine waveform is unnecessary for a small N but is required for a large N . As shown in (13) and (15), the only difference of modulated and unmodulated waveform on z exists in the fourth-order terms, where $\mathcal{E}\{\mathcal{A}\{y_I^4(t)\}\}$ has N^2 monomials with a modulation gain of 2 and $\mathcal{A}\{y_P^4(t)\}$ has $(2N^3 + N)/3$

Fig. 6. WPT-optimized waveform amplitudes versus N for $M = 1$, $L = 20$, $\sigma_n = -40$ dBm, $B = 1$ MHz and $d_H = d_V = 2$ m.

Fig. 7. Average R-E region and splitting ratio versus σ_n for $M = 1$, $N = 16$, $L = 20$, $B = 1$ MHz and $d_H = d_V = 2$ m.

monomials without modulation gain. Therefore, superposed waveform enlarges the R-E region for a sufficiently large N (typically no smaller than 4). However, an excessively large N not only increases complexity but also operates out of the small-signal harvester model, thus become prohibitive. *Second*, the R-E region is convex for $N = 2, 4$ and concave-convex for $N = 8, 16$. This has the consequence that PS outperforms TS for a small N and is outperformed for a large N . When N is in between, the optimal strategy is a combination of both, i.e. a time sharing between the WPT point and the tangent WIPT point obtained by PS. Compared with the linear harvester model that requires no dedicated power waveform and always prefer PS, the rectifier nonlinearity enlarges the R-E region by favouring a different waveform and transceiving strategy, both heavily depends on N .

The influence of the average noise power on the average

Fig. 8. Average R-E region versus d_H for $M = 1$, $N = 16$, $L = 20$, $\sigma_n = -40$ dBm, $B = 1$ MHz and $d_V = 2$ m.

R-E region is investigated in Fig. 7. We *first* note that for a large number of subbands, the R-E region is approximately concave for a high noise level and approximately convex for a low noise level. Hence, TS is preferred at low SNR while PS is preferred at high SNR. This is because at a low SNR, the capacity-achieving WF algorithm tends to allocate more power to few strongest subbands. As the rate constraint \bar{R} decreases, more subbands are activated to further boost the harvested energy via the coupling effect by rectifier nonlinearity. *Second*, there exists a turning point in the R-E region especially for a small noise ($\sigma_n \leq -40$ dBm). The reason is that when \bar{R} departs slightly from the maximum achievable rate, the algorithm mainly adjusts the splitting ratio ρ rather than put more weight on the multisine waveform, as a small amplitude could be inefficient for energy maximization. On the other hand, as \bar{R} further reduces, a modulated waveform with a very large ρ could be outperformed by a superposed waveform with a smaller ρ , due to advantage the of multisine. The result highlights the benefit of multisine and the necessity of joint optimization of waveform and splitting ratio.

In Fig. 8, we compare the average R-E region achieved by different AP-IRS horizontal distance d_H . A *first* observation is that, different from the active amplify-and-forward relay that achieves optimal performance when developed around the midpoint, placing the IRS closer to either the AP or the user would further improve the R-E tradeoff. It origins from the product-distance path loss model that applies to finite-size element reflection. As shown in Fig. 9, although the piecewise TGN path loss model further penalizes large distance (greater than 10 m for model D), it is still beneficial to have a short-long or long-short transmission setup, since signal attenuation increases fast at a short distance and experiences marginal effect at a long distance. On the other hand, it also suggests that developing an IRS next to the AP can effectively extend the operation range of SWIPT systems. Considering the passive characteristic of IRS, opportunities are that it can be directly supported by the SWIPT network. A *second* observation is

Fig. 9. Path loss versus distance for IEEE TGN channel model D.

Fig. 10. Average R-E region versus M for $N = 16$, $L = 20$, $\sigma_n = -40$ dBm, $B = 1$ MHz and $d_H = d_V = 2$ m.

that there exist two optimal IRS development locations that maximizes the path loss production $\Lambda_I \Lambda_R$. It implies that more than one IRS may be implemented to further enlarge the R-E region, one attached to the AP and one attached to the IRS.

The number of transmit antennas M and IRS reflectors L influence the average R-E tradeoff as revealed in 10 and Fig. 11. *First*, it is observed that adding either active or passive elements benefits both information and power transmission while preserving the concavity-convexity of the R-E region. This is because increasing M or L indeed enhances the equivalent composite channel strength such that only the magnitude of the terms in (11) is amplified. Therefore, it is concluded that the number of active and passive elements have no impact on the waveform preference and transceiving strategy. *Second*, the R-E benefit of passive beamforming scales faster than that of active beamforming. This behavior is more obvious in Fig. 12 and 13 that illustrate the performance of WIT and WPT versus M and L . For the active MRT beamforming,

Fig. 11. Average R-E region versus L for $M = 1$, $N = 16$, $\sigma_n = -40$ dBm, $B = 1$ MHz and $d_H = d_V = 2$ m.

Fig. 12. Average WIT SNR and WPT DC current versus M for $L = 20$, $N = 16$, $\sigma_n = -40$ dBm, $B = 1$ MHz, $d_H = 0$ and $d_V = 0.5$ m.

doubling M brings a 3 dB gain at the average output SNR, corresponding to a transmit array gain of M and a doubled harvester input power. Due to the rectifier nonlinearity, the output DC current ends up with a nearly four-time (12 dB) increase, validating the active scaling law in the order of M^2 [8]. On the other hand, when the IRS is very closed to the transmitter or the receiver, doubling L can bring a SNR boost up to 6 dB, corresponding to an reflect array gain of L^2 . An interpretation is that the IRS collects L signal copies with a receive array gain L , then performs an equal gain reflection with a transmit array gain L , achieving a total gain of L^2 . As a consequence, doubling L brings a four-fold boost on the received signal power that further amplifies the harvested DC current by 16 times (24 dB), suggesting a passive scaling law in the order of L^4 . Besides, by considering harvester nonlinearity, the proposed design brings a 20 dB increase in the output DC current over conventional linear perspective.

Fig. 13. Average WIT SNR and WPT DC current versus L for $M = 1$, $N = 16$, $\sigma_n = -40$ dBm, $B = 1$ MHz, $d_H = 0$ and $d_V = 0.5$ m.

However, the diode nonlinear model is based on a small-signal expansion and the input-output relationship would be linear in the high-power regime. These results emphasize the effectiveness of passive beamforming and the importance of modelling rectifier nonlinearity in the system design. *Third*, using only few transmit antenna can achieve the performance of numerous reflectors in a much lower complexity. The reason is that the system performance in our setup is dominated by the AP-user direct link, with the optimal active beamformer obtained in closed form. As shown in Fig. 9, the direct path loss Λ_D is in the scope of 10^{-7} while the extra path loss product $\Lambda_I \Lambda_R$ is below 10^{-10} . Therefore, although increasing L can significantly enhance the AP-IRS-user extra channel, its amplitude is still too small compared with the direct channel such that increasing M can be more efficient for a practical configuration. Another explanation is that the RF-chains of active antennas provide design flexibility in the frequency domain while the frequency-flat characteristic of IRS restricts its benefit for broadband transmission. On the contrary, a large number of active antennas suffer from channel hardening while the IRS can use adaptive reflection to potentially mitigate the effect. As a consequence, active beamforming is more effective for small-scale SWIPT where the direct channel dominates the transmission, and passive beamforming can be more effective for large-scale SWIPT where the extra channel dominates the transmission.

Fig. 14 and 15 explore the average R-E region under different IRS configuration for narrowband transmission and broadband transmission. The adaptive scheme jointly optimize the waveform, splitting ratio, active beamforming and passive beamforming alternatively for each points in the R-E boundary. In comparison, the WIT/WPT-based schemes only perform alternating optimization for the right-most/left-most points, then fix the IRS and update the rest to obtain the R-E curve. To gain some insight into the IRS behavior, we compare the results above to that of no IRS and the ideal FS IRS, where each element is assumed to have an independent reflection

Fig. 14. Average R-E region for adaptive, ideal, fixed and no IRS over $B = 1$ MHz for $M = 1$, $N = 16$, $L = 20$, $\sigma_n = -40$ dBm and $d_H = d_V = 2$ m.

Fig. 15. Average R-E region for adaptive, ideal, fixed and no IRS over $B = 10$ MHz for $M = 1$, $N = 16$, $L = 20$, $\sigma_n = -40$ dBm and $d_H = d_V = 2$ m.

coefficient for each subband, accounting for a total design flexibility of NL . Since the IRS only control the phase of the concatenated channel, for single transmit antenna AP, the optimal strategy for each FS reflector would be aligning the AP-IRS-user and AP-user channel over all subbands, namely

$$\theta_{l,n}^* = e^{j \arg(h_{D,n}/h_{I,n,l}h_{R,n,l})}, \quad \forall n, l. \quad (37)$$

First, it is observed that the presence of IRS effectively enlarges the achievable R-E region for both narrowband and broadband transmissions. This is because IRS creates and controls the weak extra channels for a constructive signal superposition. *Second*, the performance gaps of the adaptive, ideal and fixed IRS are negligible for narrowband transmission but obvious for broadband transmission. The reason is that when $B = 1$ MHz, the subchannel responses are very similar and the optimal ideal

reflection coefficients would almost align at all subbands. That is to say, there is no enough diversity as well as incentive for the IRS to manipulate the subchannel strength such that all four IRS strategies coincide with each other. It implies that for narrowband SWIPT, the optimal passive beamforming obtained from any R-E point is also optimal for the whole R-E boundary. On the other hand, the channel frequency selectivity becomes significant for $B = 10$ MHz, and the ideal FS IRS outperforms the others as it requires no tradeoff in subchannel alignments. Moreover, the WIT-optimized IRS tends to equalize the channel strength for all subbands as possible, due to the preference of WF strategy at high SNR. In comparison, the WPT-optimized IRS beams less towards few weakest subchannels, due to the inefficiency of small-amplitude tones in energy harvesting. In conclusion, adaptive passive beamforming is required for broadband SWIPT as information and energy receivers have different preference on the subchannel strength control.

V. CONCLUSION AND FUTURE WORKS

This paper proposes a novel multi-carrier IRS-aided downlink MISO SWIPT system to enhance the spectrum and energy efficiency of a single user. We perform a joint optimization of the waveform and active beamforming at the transmitter, the passive beamforming at the IRS, and the power splitting ratio at the receiver to enlarge the achievable R-E region. Different from the existing IRS-aided SWIPT literature, this paper leverages rectifier nonlinearity in passive beamforming design and investigates a multi-carrier transmission with practical co-localized receiver architectures. Efficient algorithms based on GP, SCA, SDR and AO techniques are numerically demonstrated feasible for all tested channel realizations under different configurations. We confirm that considering harvester nonlinearity, dedicated power waveform and beam are generally required to boost the R-E tradeoff. When developed near the transmitter, IRS can provide effective channel enhancement to enlarge the R-E region and expand the operation range. Compared with transmit antenna, IRS element has no design flexibility in the frequency domain, but the smart reflection combats channel hardening effect to further boost the array gain and power scaling laws. Finally, adaptive passive beamforming is required for broadband transmission, while the optimal IRS obtained from any R-E point is also optimal for the whole R-E region for narrowband SWIPT.

The combination of IRS and SWIPT brings many possibilities and challenges. For example, how to optimize waveform, active and passive beamforming in a multiuser SWIPT system? How can multiple IRS cooperate with each other to further benefit R-E tradeoff? How to perform channel estimation without RF-chains at the IRS? How to design IRS-aided SWIPT system for different multiple access techniques? How to implement IRS in new networks, such as cell-free massive Multiple-Input Multiple-Output (MIMO)? Can IRS operation be directly supported by SWIPT? Answers to these questions may bring a new wireless revolution.
